

Bad Universal Priors and Notions of Optimality

Jan Leike and Marcus Hutter

October 19, 2015

Abstract

A big open question of algorithmic information theory is the choice of the universal Turing machine (UTM). For Kolmogorov complexity and Solomonoff induction we have invariance theorems: the choice of the UTM changes bounds only by a constant. For the universally intelligent agent AIXI (Hutter, 2005) no invariance theorem is known. Our results are entirely negative: we discuss cases in which unlucky or adversarial choices of the UTM cause AIXI to misbehave drastically. We show that Legg-Hutter intelligence and thus balanced Pareto optimality is entirely subjective, and that every policy is Pareto optimal in the class of all computable environments. This undermines all existing optimality properties for AIXI. While it may still serve as a gold standard for AI, our results imply that AIXI is a *relative* theory, dependent on the choice of the UTM.

Keywords. AIXI, general reinforcement learning, universal Turing machine, Legg-Hutter intelligence, balanced Pareto optimality, asymptotic optimality.

1 Introduction

The choice of the universal Turing machine (UTM) has been a big open question in algorithmic information theory for a long time. While attempts have been made (Müller, 2010) no answer is in sight. The *Kolmogorov complexity* of a string, the length of the shortest program that prints this string, depends on this choice. However, there are *invariance theorems* (Li and Vitányi, 2008, Thm. 2.1.1 & Thm. 3.1.1) which state that changing the UTM changes Kolmogorov complexity only by a constant. When using the *universal prior* M introduced by Solomonoff (1964, 1978) to predict any deterministic computable binary sequence, the number of wrong predictions is bounded by (a multiple of) the Kolmogorov complexity of the sequence (Hutter, 2001). Due to the invariance theorem, changing the UTM changes the number of errors only by a constant. In this sense, compression and prediction work for any choice of UTM.

Hutter (2000, 2005) defines the universally intelligent agent AIXI, which is targeted at the *general reinforcement learning problem* (Sutton and Barto, 1998). It extends Solomonoff induction to the interactive setting. AIXI is

a Bayesian agent, using a universal prior on the set of all computable environments; actions are taken according to the maximization of expected future discounted rewards. Closely related is the intelligence measure defined by Legg and Hutter (2007), a mathematical performance measure for general reinforcement learning agents: defined as the discounted rewards achieved across all computable environments, weighted by the universal prior.

There are several known positive results about AIXI. It has been proven to be *Pareto optimal* (Hutter, 2002, Thm. 2 & Thm. 6), *balanced Pareto optimal* (Hutter, 2002, Thm. 3), and has maximal Legg-Hutter intelligence. Furthermore, AIXI asymptotically learns to predict the environment perfectly and with a small total number of errors analogously to Solomonoff induction (Hutter, 2005, Thm. 5.36), but only *on policy*: AIXI learns to correctly predict the value (expected future rewards) of its own actions, but generally not the value of counterfactual actions that it does not take.

Orseau (2010, 2013) showed that AIXI does not achieve asymptotic optimality in all computable environments. So instead, we may ask the following weaker questions. Does AIXI succeed in every partially observable Markov decision process (POMDP)/(ergodic) Markov decision process (MDP)/bandit problem/sequence prediction task? In this paper we show that without further assumptions on the UTM, we cannot answer any of the preceding questions in the affirmative. More generally, there can be no invariance theorem for AIXI. As a reinforcement learning agent, AIXI has to balance between exploration and exploitation. Acting according to any (universal) prior does not lead to enough exploration, and the bias of AIXI's prior is retained indefinitely. For bad priors this can cause serious malfunctions. However, this problem can be alleviated by adding an extra exploration component to AIXI (Lattimore, 2013, Ch. 5), similar to knowledge-seeking agents (Orseau, 2014; Orseau et al., 2013), or by the use of optimism (Sunehag and Hutter, 2012).

In Section 3 we give two examples of universal priors that cause AIXI to misbehave drastically. In case of a finite lifetime, the *indifference prior* makes all actions equally preferable to AIXI (Section 3.1). Furthermore, for any computable policy π the *dogmatic prior* makes AIXI stick to the policy π as long as expected future rewards do not fall too close to zero (Section 3.2). This has profound implications. We show in Section 4 that if we measure Legg-Hutter intelligence with respect to a *different* universal prior, AIXI scores arbitrarily close to the minimal intelligence while any computable policy can score arbitrarily close to the maximal intelligence. This makes the Legg-Hutter intelligence score and thus balanced Pareto optimality relative to the choice of the UTM. Moreover, in Section 5 we show that in the class of all computable environments, *every* policy is Pareto optimal. This undermines all existing optimality results for AIXI. We discuss the implications of these results for the quest for a *natural* universal Turing machine and optimality notions of general reinforcement learners in Section 6. A list of notation is provided in Appendix A.

2 Preliminaries and Notation

The set $\mathcal{X}^* := \bigcup_{n=0}^{\infty} \mathcal{X}^n$ is the set of all finite strings over the alphabet \mathcal{X} , the set \mathcal{X}^∞ is the set of all infinite strings over the alphabet \mathcal{X} , and the set $\mathcal{X}^\# := \mathcal{X}^* \cup \mathcal{X}^\infty$ is their union. The empty string is denoted by ϵ , not to be confused with the small positive real number ε . Given a string $x \in \mathcal{X}^\#$, we denote its length by $|x|$. For a (finite or infinite) string x of length $\geq k$, we denote with $x_{1:k}$ the first k characters of x , and with $x_{<k}$ the first $k - 1$ characters of x . The notation $x_{1:\infty}$ stresses that x is an infinite string. We write $x \sqsubseteq y$ iff x is a prefix of y , i.e., $x = y_{1:|x|}$.

In reinforcement learning, the agent interacts with an environment in cycles: at time step t the agent chooses an *action* $a_t \in \mathcal{A}$ and receives a *percept* $e_t = (o_t, r_t) \in \mathcal{E}$ consisting of an *observation* $o_t \in \mathcal{O}$ and a real-valued *reward* $r_t \in \mathbb{R}$; the cycle then repeats for $t + 1$. A *history* is an element of $(\mathcal{A} \times \mathcal{E})^*$. We use $\mathfrak{x} \in \mathcal{A} \times \mathcal{E}$ to denote one interaction cycle, and $\mathfrak{x}_{<t}$ to denote a history of length $t - 1$. The goal in reinforcement learning is to maximize total discounted rewards. A *policy* is a function $\pi : (\mathcal{A} \times \mathcal{E})^* \rightarrow \mathcal{A}$ mapping each history to the action taken after seeing this history. A history $\mathfrak{x}_{<t}$ is *consistent with policy* π iff $\pi(\mathfrak{x}_{<k}) = a_k$ for all $k < t$.

A function $f : \mathcal{X}^* \rightarrow \mathbb{R}$ is *lower semicomputable* iff the set $\{(x, q) \in \mathcal{X}^* \times \mathbb{Q} \mid f(x) > q\}$ is recursively enumerable. A *conditional semimeasure* ν is a probability measure over finite and infinite strings of percepts given actions as input where $\nu(e_{<t} \parallel a_{1:\infty})$ denotes the probability of receiving percepts $e_{<t}$ when taking actions $a_{1:\infty}$. Formally, ν maps \mathcal{A}^∞ to a probability distribution over $\mathcal{E}^\#$. Thus the environment might assign positive probability to finite percept sequences. One possible interpretation for this is that there is a non-zero chance that the environment ends: it simply does not produce a new percept. Another possible interpretation is that there is a non-zero chance of death for the agent. However, nothing hinges on the interpretation; the use of (unnormalized) semimeasures is primarily a technical trick.

The conditional semimeasure ν is *chronological* iff the first $t - 1$ percepts are independent of future actions a_k for $k \geq t$, i.e., $\nu(e_{<t} \parallel a_{1:k}) = \nu(e_{<t} \parallel a_{<t})$. Despite their name, conditional semimeasures do not denote a conditional probability; ν is not a joint probability distribution over actions and percepts. We model environments as lower semicomputable chronological conditional semimeasures (LSCCS) (Hutter, 2005, Sec. 5.1.1); the class of all such environments is denoted as $\mathcal{M}_{\text{LSC}}^{\text{CCS}}$. We also use the larger set of all chronological conditional semimeasures \mathcal{M}^{CCS} .

A *universal prior* is a function $w : \mathcal{M}_{\text{LSC}}^{\text{CCS}} \rightarrow [0, 1]$ such that $w_\nu := w(\nu) > 0$ for all $\nu \in \mathcal{M}_{\text{LSC}}^{\text{CCS}}$ and $\sum_{\nu \in \mathcal{M}_{\text{LSC}}^{\text{CCS}}} w_\nu \leq 1$. A universal prior w gives rise to a *universal mixture*,

$$\xi(e_{<t} \parallel a_{<t}) := \sum_{\nu \in \mathcal{M}_{\text{LSC}}^{\text{CCS}}} w_\nu \nu(e_{<t} \parallel a_{<t}). \quad (1)$$

If the universal prior is lower semicomputable, then the universal mixture ξ is

an LSCCCS, i.e., $\xi \in \mathcal{M}_{\text{LSC}}^{\text{CCS}}$. From a given universal monotone Turing machine U (Li and Vitányi, 2008, Sec. 4.5.2) we can get a universal mixture ξ in two ways. First, we can use (1) with the prior given by $w_\nu := 2^{-K(\nu)}$, where $K(\nu)$ is the *Kolmogorov complexity* of ν 's index in the enumeration of all LSCCCSs (Li and Vitányi, 2008, Eq. 4.11). Second, we can define it as the probability that the universal monotone Turing machine U generates $e_{<t}$ when fed with $a_{<t}$ and uniformly random bits:

$$\xi(e_{<t} \parallel a_{<t}) := \sum_{p: e_{<t} \sqsubseteq U(p, a_{<t})} 2^{-|p|} \quad (2)$$

Both definitions are equivalent, but not necessarily equal (Wood et al., 2011, Lem. 10 & Lem. 13).

Lemma 1 (Mixing Mixtures). *Let $q, q' \in \mathbb{Q}$ such that $q > 0$, $q' \geq 0$, and $q + q' \leq 1$. Let w be any lower semicomputable universal prior, let ξ be the universal mixture for w , and let ρ be an LSCCCS. Then $\xi' := q\xi + q'\rho$ is an LSCCCS and a universal mixture.*

Proof. ξ' is given by the universal prior w' with $w' := qw + q'\mathbb{1}_\rho$. \square

Throughout this paper, we make the following assumptions.

Assumption 2. (a) *Rewards are bounded between 0 and 1.*

(b) *The set of actions \mathcal{A} and the set of percepts \mathcal{E} are both finite.*

We fix a *discount function* $\gamma : \mathbb{N} \rightarrow \mathbb{R}$ with $\gamma_t := \gamma(t) \geq 0$ and $\sum_{t=1}^{\infty} \gamma_t < \infty$. The *discount normalization factor* is defined as $\Gamma_t := \sum_{i=t}^{\infty} \gamma_i$. There is no requirement that $\gamma_t > 0$ or $\Gamma_t > 0$. If $m := \min\{t \mid \Gamma_{t+1} = 0\}$ exists, we say the agent has a *finite lifetime* m and does not care what happens afterwards.

Definition 3 (Value Function). The *value* of a policy π in an environment ν given history $\mathfrak{x}_{<t}$ is defined as $V_\nu^\pi(\mathfrak{x}_{<t}) := V_\nu^\pi(\mathfrak{x}_{<t}\pi(\mathfrak{x}_{<t}))$ and

$$V_\nu^\pi(\mathfrak{x}_{<t}a_t) := \frac{1}{\Gamma_t} \sum_{e_t \in \mathcal{E}} (\gamma_t r_t + \Gamma_{t+1} V_\nu^\pi(\mathfrak{x}_{1:t})) \nu(e_{1:t} \mid e_{<t} \parallel a_{1:t})$$

if $\Gamma_t > 0$ and $V_\nu^\pi(\mathfrak{x}_{<t}) := 0$ if $\Gamma_t = 0$. The *optimal value* is defined as $V_\nu^*(h) := \sup_\pi V_\nu^\pi(h)$.

Definition 4 (Optimal Policy (Hutter, 2005, Def. 5.19 & 5.30)). A policy π is *optimal in environment ν* (ν -*optimal*) iff for all histories π attains the optimal value: $V_\nu^\pi(h) = V_\nu^*(h)$ for all $h \in (\mathcal{A} \times \mathcal{E})^*$. The action $\pi(h)$ is an *optimal action* iff $\pi(h) = \pi_\nu^*(h)$ for some ν -optimal policy π_ν^* .

Formally, AIXI is defined as a policy π_ξ^* that is optimal in the universal mixture ξ . Since there can be more than one ξ -optimal policy, this definition is not unique. If there two optimal actions $\alpha \neq \beta \in \mathcal{A}$, we call it an *argmax tie*. Which action we take in case of a tie (how we break the tie) is irrelevant and

can be arbitrary. We assumed that the discount function is summable, rewards are bounded (Assumption 2a), and actions and percepts spaces are both finite (Assumption 2b). Therefore an optimal policy exists for every environment $\nu \in \mathcal{M}_{\text{LSC}}^{\text{CCS}}$ (Lattimore and Hutter, 2014, Thm. 10), in particular for any universal mixture ξ .

Lemma 5 (Discounted Values (Lattimore, 2013, Lem. 2.5)). *If two policies π_1 and π_2 coincide for the first k steps ($\pi_1(\mathfrak{x}_{<t}) = \pi_2(\mathfrak{x}_{<t})$ for all histories $\mathfrak{x}_{<t}$ consistent with π_1 and $t \leq k$), then*

$$|V_{\nu}^{\pi_1}(\epsilon) - V_{\nu}^{\pi_2}(\epsilon)| \leq \frac{\Gamma_{k+1}}{\Gamma_1} \text{ for all environments } \nu \in \mathcal{M}^{\text{CCS}}.$$

Proof. Since the policies π_1 and π_2 coincide for the first k steps, they produce the same expected rewards for the first k steps. Therefore

$$\begin{aligned} |V_{\nu}^{\pi_1}(\epsilon) - V_{\nu}^{\pi_2}(\epsilon)| &= \left| \sum_{e_{1:k}} \frac{\Gamma_{k+1}}{\Gamma_1} (V_{\nu}^{\pi_1}(\mathfrak{x}_{1:k}) - V_{\nu}^{\pi_2}(\mathfrak{x}_{1:k})) \nu(e_{1:k} \parallel a_{1:k}) \right| \\ &\leq \sum_{e_{1:k}} \frac{\Gamma_{k+1}}{\Gamma_1} |V_{\nu}^{\pi_1}(\mathfrak{x}_{1:k}) - V_{\nu}^{\pi_2}(\mathfrak{x}_{1:k})| \nu(e_{1:k} \parallel a_{1:k}) \leq \frac{\Gamma_{k+1}}{\Gamma_1}, \end{aligned}$$

where $a_t := \pi_1(\mathfrak{x}_{<t}) = \pi_2(\mathfrak{x}_{<t})$ for all $t \leq k$. The last inequality follows since ν is a semimeasure, $0 \leq V_{\nu}^{\pi} \leq 1$ and hence $|V_{\nu}^{\pi_1}(\mathfrak{x}_{1:k}) - V_{\nu}^{\pi_2}(\mathfrak{x}_{1:k})| \leq 1$. \square

3 Bad Universal Priors

3.1 The Indifference Prior

In this section we consider AIXI with a finite lifetime m , i.e., $\Gamma_{m+1} = 0$. The following theorem constructs the *indifference prior*, a universal prior ξ' that causes argmax ties for the first m steps. Since we use a discount function that only cares about the first m steps, all policies are ξ' -optimal policies. Thus AIXI's behavior only depends on how we break argmax ties.

Theorem 6 (Indifference Prior). *If there is an m such that $\Gamma_{m+1} = 0$, then there is a universal mixture ξ' such that all policies are ξ' -optimal.*

Proof. First, we assume that the action space is binary, $\mathcal{A} = \{0, 1\}$. Let U be the reference UTM and define the UTM U' by

$$U'(s_{1:m}p, a_{1:t}) := U(p, a_{1:t} \text{ XOR } s_{1:t}),$$

where $s_{1:m}$ is a binary string of length m and $s_k := 0$ for $k > m$. (U' has no programs of length $\leq m$.) Let ξ' be the universal mixture given by U' according to (2).

$$\xi'(e_{1:m} \parallel a_{1:m}) = \sum_{p: e_{1:m} \sqsubseteq U'(p, a_{1:m})} 2^{-|p|}$$

$$\begin{aligned}
&= \sum_{s_{1:m} p' : e_{1:m} \sqsubseteq U'(s_{1:m} p', a_{1:m})} 2^{-m-|p'|} \\
&= \sum_{s_{1:m}} \sum_{p' : e_{1:m} \sqsubseteq U(p', a_{1:m} \text{ xor } s_{1:m})} 2^{-m-|p'|} \\
&= \sum_{s_{1:m}} \sum_{p' : e_{1:m} \sqsubseteq U(p', s_{1:m})} 2^{-m-|p'|},
\end{aligned}$$

which is independent of $a_{1:m}$. Hence the first m percepts are independent of the first m actions. But the percepts' rewards after time step m do not matter since $\Gamma_{m+1} = 0$ (Lemma 5). Because the environment is chronological, the value function must be independent of all actions. Thus every policy is ξ' -optimal.

For finite action spaces \mathcal{A} with more than 2 elements, the proof works analogously by making \mathcal{A} a cyclic group and using the group operation instead of xor. \square

The choice of U' in the proof of Theorem 6 is *unnatural* since its shortest program has length greater than m . Moreover, the choice of U' depends on m . If we increase AIXI's lifetime while fixing the UTM U' , Theorem 6 no longer holds. For Solomonoff induction, there is an analogous problem: when using Solomonoff's prior M to predict a deterministic binary sequence x , we make at most $K(x)$ errors. In case the shortest program has length $> m$, there is no guarantee that we make less than m errors.

3.2 The Dogmatic Prior

In this section we define a universal prior that assigns very high probability of going to hell (reward 0 forever) if we deviate from a given computable policy π . For a Bayesian agent like AIXI, it is thus only worth deviating from the policy π if the agent thinks that the prospects of following π are very poor already. We call this prior the *dogmatic prior*, because the fear of going to hell makes AIXI conform to any arbitrary 'dogmatic ideology' π . AIXI will only break out if it expects π to give very low future payoff; in that case the agent does not have much to lose.

Theorem 7 (Dogmatic Prior). *Let π be any computable policy, let ξ be any universal mixture, and let $\varepsilon > 0$. There is a universal mixture ξ' such that for any history h consistent with π and $V_\xi^\pi(h) > \varepsilon$, the action $\pi(h)$ is the unique ξ' -optimal action.*

The proof proceeds by constructing a universal mixture that assigns disproportionately high probability to an environment ν that sends any policy deviating from π to hell. Importantly, the environment ν produces observations according to the universal mixture ξ . Therefore ν is indistinguishable from ξ on the policy π , so the posterior belief in ν is equal to the prior belief in ν .

Proof. We assume $(0, 0) \in \mathcal{E}$. Let π be any computable policy and define

$$\nu(e_{1:t} \parallel a_{1:t}) := \begin{cases} \xi(e_{1:t} \parallel a_{1:t}), & \text{if } a_k = \pi(\mathfrak{x}_{<k}) \forall k \leq t, \\ \xi(e_{<k} \parallel a_{<k}), & \text{if } k := \min\{i \mid a_i \neq \pi(\mathfrak{x}_{<i})\} \text{ exists} \\ & \text{and } e_i = (0, 0) \forall i \in \{k, \dots, t\}, \\ 0, & \text{otherwise.} \end{cases}$$

The environment ν mimics the universal environment ξ until it receives an action that the policy π would not take. From then on, it provides rewards 0. Since ξ is a LSCCS and π is a computable policy, we have that $\nu \in \mathcal{M}_{\text{LSC}}^{\text{CCS}}$.

Without loss of generality we assume that ε is computable, otherwise we make it slightly smaller. Thus $\xi' := \frac{1}{2}\nu + \frac{\varepsilon}{2}\xi$ is a universal mixture according to Lemma 1.

Let $h \in (\mathcal{A} \times \mathcal{E})^*$ be any history consistent with π such that $V_\xi^\pi(h) > \varepsilon$. In the following, we use the shorthand notation $\rho(h) := \rho(e_{1:t} \parallel a_{1:t})$ for a conditional semimeasure ρ and $h =: \mathfrak{x}_{1:t}$. Since ν gives observations and rewards according to ξ , we have $\nu(h) = \xi(h)$, and thus the posterior weight $w_\nu(h)$ of ν in $V_{\xi'}^\pi(h)$ is constant while following π :

$$\frac{w_\nu(h)}{w_\nu} := \frac{\nu(h)}{\xi'(h)} = \frac{\xi(h)}{\xi'(h)} = \frac{\xi(h)}{\frac{1}{2}\nu(h) + \frac{\varepsilon}{2}\xi(h)} = \frac{\xi(h)}{\frac{1}{2}\xi(h) + \frac{\varepsilon}{2}\xi(h)} = \frac{2}{1 + \varepsilon}$$

Therefore linearity of $V_\nu^{\tilde{\pi}}$ in ν (Hutter, 2005, Thm. 5.31, proved in Appendix B) implies that for all $a \in \mathcal{A}$,

$$V_{\xi'}^\pi(ha) = w_\nu(h)V_\nu^\pi(ha) + w_\xi(h)V_\xi^\pi(ha) = \frac{1}{1+\varepsilon}V_\nu^\pi(ha) + \frac{\varepsilon}{1+\varepsilon}V_\xi^\pi(ha). \quad (3)$$

Let $\alpha := \pi(h)$ be the next action according to π , and let $\beta \neq \alpha$ be any other action. We have that $V_\nu^\pi = V_\xi^\pi$ by definition of ν , therefore

$$V_{\xi'}^\pi(h\alpha) \stackrel{(3)}{=} \frac{1}{1+\varepsilon}V_\nu^\pi(h\alpha) + \frac{\varepsilon}{1+\varepsilon}V_\xi^\pi(h\alpha) = \frac{1}{1+\varepsilon}V_\xi^\pi(h\alpha) + \frac{\varepsilon}{1+\varepsilon}V_\xi^\pi(h\alpha) = V_\xi^\pi(h\alpha) \quad (4)$$

We get that $V_{\xi'}^*(h\alpha) > V_{\xi'}^*(h\beta)$:

$$\begin{aligned} V_{\xi'}^*(h\alpha) &\geq V_{\xi'}^\pi(h\alpha) \stackrel{(4)}{=} V_\xi^\pi(h\alpha) = V_\xi^\pi(h) > \varepsilon, \\ V_{\xi'}^*(h\beta) &\stackrel{(3)}{=} \frac{1}{1+\varepsilon}V_\nu^{\pi^*}(h\beta) + \frac{\varepsilon}{1+\varepsilon}V_\xi^{\pi^*}(h\beta) = \frac{\varepsilon}{1+\varepsilon}V_\xi^{\pi^*}(h\beta) \leq \frac{\varepsilon}{1+\varepsilon} < \varepsilon, \end{aligned}$$

Hence the action α taken by π is the only ξ' -optimal action for the history h . \square

Corollary 8 (AIXI Emulating Computable Policies). *Let $\varepsilon > 0$ and let π be any computable policy. There is a universal mixture ξ' such that for any ξ' -optimal policy $\pi_{\xi'}^*$ and for any (not necessarily computable) environment $\nu \in \mathcal{M}^{\text{CCS}}$,*

$$\left| V_\nu^{\pi_{\xi'}^*}(\varepsilon) - V_\nu^\pi(\varepsilon) \right| < \varepsilon.$$

Proof. Let $\varepsilon > 0$. Since $\Gamma_k \rightarrow 0$ as $k \rightarrow \infty$, we can choose k large enough such that $\Gamma_{k+1}/\Gamma_1 < \varepsilon$. Let $\varepsilon' > 0$ be small enough such that $V_\xi^\pi(h) > \varepsilon'$ for all h with $|h| \leq k$. This is possible since $V_\xi^\pi(h) > 0$ for all h and the set of histories of length $\leq k$ is finite because of Assumption 2b. We use the dogmatic prior from Theorem 7 to construct a universal mixture ξ' for the policy π and $\varepsilon' > 0$. Thus for any history $h \in (\mathcal{A} \times \mathcal{E})^*$ consistent with π and $|h| \leq k$, the action $\pi(h)$ is the only ξ' -optimal action. The claim now follows from Lemma 5. \square

Corollary 9 (With Finite Lifetime Every Policy is an AIXI). *If $\Gamma_{m+1} = 0$ for some $m \in \mathbb{N}$, then for any policy π there is a universal mixture ξ' such that $\pi(h)$ is the only ξ' -optimal action for all histories h consistent with π and $|h| \leq m$.*

In contrast to Theorem 6 where every policy is ξ' -optimal for a fixed universal mixture ξ' , Corollary 9 gives a different universal mixture ξ' for every policy π such that π is the only ξ' -optimal policy.

Proof. Analogously to the proof of Corollary 8, let $\varepsilon' > 0$ be small enough such that $V_\xi^\pi(h) > \varepsilon'$ for all h with $|h| \leq m$. Again, we use the dogmatic prior from Theorem 7 to construct a universal mixture ξ' for the policy π and $\varepsilon' > 0$. Thus for any history $h \in (\mathcal{A} \times \mathcal{E})^*$ consistent with π and $|h| \leq m$, the action $\pi(h)$ is the only ξ' -optimal action. \square

4 Consequences for Legg-Hutter Intelligence

The aim of the Legg-Hutter intelligence measure is to formalize the intuitive notion of intelligence mathematically. If we take intelligence to mean *an agent's ability to achieve goals in a wide range of environments* (Legg and Hutter, 2007), and we weigh environments according to the universal prior, then the intelligence of a policy π corresponds to the value that π achieves in the corresponding universal mixture. We use the results from the previous section to illustrate some problems with this intelligence measure in the absence of a *natural* UTM.

Definition 10 (Legg-Hutter Intelligence (Legg and Hutter, 2007)). The *intelligence*¹ of a policy π is defined as

$$\Upsilon_\xi(\pi) := \sum_{\nu \in \mathcal{M}_{\text{LSC}}^{\text{CCS}}} w_\nu V_\nu^\pi(\epsilon) = V_\xi^\pi(\epsilon).$$

Typically, the index ξ is omitted when writing Υ . However, in this paper we consider the intelligence measure with respect to different universal mixtures, therefore we make this dependency explicit.

Because the value function is scaled to be in the interval $[0, 1]$, intelligence is a real number between 0 and 1. Legg-Hutter intelligence is linked to *balanced*

¹ Legg and Hutter (2007) consider a subclass of $\mathcal{M}_{\text{LSC}}^{\text{CCS}}$, the class of computable *measures*, and do not use discounting explicitly.

Figure 1: The Legg-Hutter intelligence measure assigns values within the closed interval $[\underline{\Upsilon}_\xi, \overline{\Upsilon}_\xi]$; the assigned values are depicted in orange. By Theorem 11, computable policies are dense in this orange set.

Pareto optimality: a policy is said to be *balanced Pareto optimal* iff it scores the highest intelligence score:

$$\overline{\Upsilon}_\xi := \sup_{\pi} \Upsilon_\xi(\pi) = \Upsilon_\xi(\pi_\xi^*).$$

AIXI is balanced Pareto optimal (Hutter, 2005, Thm. 5.24). It is just as hard to score very high on the Legg-Hutter intelligence measure as it is to score very low: we can always turn a reward minimizer into a reward maximizer by inverting the rewards $r'_t := 1 - r_t$. Hence the lowest possible intelligence score is achieved by AIXI's twin sister, a ξ -expected reward minimizer:

$$\underline{\Upsilon}_\xi := \inf_{\pi} \Upsilon_\xi(\pi).$$

The heaven environment (reward 1 forever) and the hell environment (reward 0 forever) are computable and thus in the environment class $\mathcal{M}_{\text{LSC}}^{\text{CCS}}$; therefore it is impossible to get a reward 0 or reward 1 in every environment. Consequently, for all policies π ,

$$0 < \underline{\Upsilon}_\xi \leq \Upsilon_\xi(\pi) \leq \overline{\Upsilon}_\xi < 1. \quad (5)$$

See Figure 1. It is natural to fix the policy `random` that takes actions uniformly at random to have an intelligence score of $1/2$ by choosing a ‘symmetric’ universal prior (Legg and Veness, 2013).

AIXI is not computable (Leike and Hutter, 2015, Thm. 14), hence there is no computable policy π such that $\Upsilon_\xi(\pi) = \underline{\Upsilon}_\xi$ or $\Upsilon_\xi(\pi) = \overline{\Upsilon}_\xi$ for any universal mixture ξ . But the next theorem tells us that computable policies can come arbitrarily close. This is no surprise: by Lemma 5 we can do well on a Legg-Hutter intelligence test simply by memorizing what AIXI would do for the first k steps; as long as k is chosen large enough such that discounting makes the remaining rewards contribute very little to the value function.

Theorem 11 (Computable Policies are Dense). *The set*

$$\{\Upsilon_\xi(\pi) \mid \pi \text{ is a computable policy}\}$$

is dense in the set of intelligence scores

$$\{\Upsilon_\xi(\pi) \mid \pi \text{ is a policy}\}.$$

Proof. Let π be any policy and let $\varepsilon > 0$. We need to show that there is a computable policy $\tilde{\pi}$ with $|\Upsilon_\xi(\tilde{\pi}) - \Upsilon_\xi(\pi)| < \varepsilon$. We choose k large enough such that $\Gamma_{k+1}/\Gamma_1 < \varepsilon$. Let $\alpha \in \mathcal{A}$ be arbitrary and define the policy

$$\tilde{\pi}(h) := \begin{cases} \pi(h) & \text{if } |h| \leq k, \text{ and} \\ \alpha & \text{otherwise.} \end{cases}$$

The policy $\tilde{\pi}$ is computable because we can store the actions of π for the first k steps in a lookup table. By Lemma 5 we get $|\Upsilon_\xi(\pi) - \Upsilon_\xi(\tilde{\pi})| = |V_\xi^\pi(\varepsilon) - V_\xi^{\tilde{\pi}}(\varepsilon)| \leq \Gamma_{k+1}/\Gamma_1 < \varepsilon$. \square

Remark 12 (Intelligence is not Dense in $[\underline{\Upsilon}_\xi, \overline{\Upsilon}_\xi]$). The intelligence values of policies are generally not dense in the interval $[\underline{\Upsilon}_\xi, \overline{\Upsilon}_\xi]$. We show this by defining an environment ν where the first action determines whether the agent goes to heaven or hell: action α leads to heaven and action β leads to hell. The semimeasure $\xi' := 0.999\nu + 0.001\xi$ is a universal mixture by Lemma 1. Let π be any policy. If π takes action α first, then $\Upsilon_{\xi'}(\pi) > 0.999$. If π takes action β first, then $\Upsilon_{\xi'}(\pi) < 0.001$. Hence there are no policies that score an intelligence value in the closed interval $[0.001, 0.999]$.

Legg-Hutter intelligence is measured with respect to a fixed UTM. AIXI is the most intelligent policy *if it uses the same UTM*. But if we build AIXI with a dogmatic prior, its intelligence score can be arbitrary close to the minimum intelligence score $\underline{\Upsilon}_\xi$.

Corollary 13 (Some AIXIs are Stupid). *For any universal mixture ξ and every $\varepsilon > 0$, there is a universal mixture ξ' such that $\Upsilon_\xi(\pi_{\xi'}^*) < \underline{\Upsilon}_\xi + \varepsilon$.*

Proof. Let $\varepsilon > 0$. According to Theorem 11, there is a computable policy π such that $\Upsilon_\xi(\pi) < \underline{\Upsilon}_\xi + \varepsilon/2$. From Corollary 8 we get a universal mixture ξ' such that $|\Upsilon_\xi(\pi_{\xi'}^*) - \Upsilon_\xi(\pi)| = |V_\xi^{\pi_{\xi'}^*}(\varepsilon) - V_\xi^\pi(\varepsilon)| < \varepsilon/2$, hence $|\Upsilon_\xi(\pi_{\xi'}^*) - \underline{\Upsilon}_\xi| \leq |\Upsilon_\xi(\pi_{\xi'}^*) - \Upsilon_\xi(\pi)| + |\Upsilon_\xi(\pi) - \underline{\Upsilon}_\xi| < \varepsilon/2 + \varepsilon/2 = \varepsilon$. \square

We get the same result if we fix AIXI, but rig the intelligence measure.

Corollary 14 (AIXI is Stupid for Some Υ). *For any ξ -optimal policy π_ξ^* and for every $\varepsilon > 0$ there is a universal mixture ξ' such that $\Upsilon_{\xi'}(\pi_\xi^*) \leq \varepsilon$ and $\overline{\Upsilon}_{\xi'} \geq 1 - \varepsilon$.*

Proof. Let $a_1 := \pi_\xi^*(\varepsilon)$ be the first action that π_ξ^* takes. We define an environment ν such that taking the first action a_1 leads to hell and taking any other first action leads to heaven as in Remark 12. With Lemma 1 we define the universal mixture $\xi' := (1 - \varepsilon)\nu + \varepsilon\xi$. Since π_ξ^* takes action a_1 first, it goes to hell, i.e., $V_\nu^{\pi_\xi^*}(\varepsilon) = 0$. Hence

$$\Upsilon_{\xi'}(\pi_\xi^*) = V_{\xi'}^{\pi_\xi^*}(\varepsilon) = (1 - \varepsilon)V_\nu^{\pi_\xi^*}(\varepsilon) + \varepsilon V_\xi^{\pi_\xi^*}(\varepsilon) \leq \varepsilon.$$

For any policy π that takes an action other than a_1 first, we get

$$\Upsilon_{\xi'}(\pi) = V_{\xi'}^\pi(\varepsilon) = (1 - \varepsilon)V_\nu^\pi(\varepsilon) + \varepsilon V_\xi^\pi(\varepsilon) \geq 1 - \varepsilon. \quad \square$$

On the other hand, we can make any computable policy smart if we choose the right universal mixture. In particular, we get that there is a universal mixture such that ‘do nothing’ is the most intelligent policy save for some ε !

Corollary 15 (Computable Policies can be Smart). *For any computable policy π and any $\varepsilon > 0$ there is a universal mixture ξ' such that $\Upsilon_{\xi'}(\pi) > \bar{\Upsilon}_{\xi'} - \varepsilon$.*

Proof. Corollary 8 yields a universal mixture ξ' with $|\bar{\Upsilon}_{\xi'} - \Upsilon_{\xi'}(\pi)| = |V_{\xi'}^*(\varepsilon) - V_{\xi'}^\pi(\varepsilon)| < \varepsilon$. \square

5 Pareto Optimality

In Section 3 we have seen examples for bad choices of the universal prior. But we know that for any universal prior, AIXI is *Pareto optimal* (Hutter, 2002). Here we show that Pareto optimality is not a useful criterion for optimality since for any environment class containing $\mathcal{M}_{\text{LSC}}^{\text{CCS}}$, all policies are Pareto optimal.

Definition 16 (Pareto Optimality (Hutter, 2005, Def. 5.22)). Let \mathcal{M} be a set of environments. A policy π is *Pareto optimal in the set of environments \mathcal{M}* iff there is no policy $\tilde{\pi}$ such that $V_\nu^{\tilde{\pi}}(\varepsilon) \geq V_\nu^\pi(\varepsilon)$ for all $\nu \in \mathcal{M}$ and $V_\rho^{\tilde{\pi}}(\varepsilon) > V_\rho^\pi(\varepsilon)$ for at least one $\rho \in \mathcal{M}$.

Theorem 17 (AIXI is Pareto Optimal (Hutter, 2005, Thm. 5.32)). *A ξ -optimal policy is Pareto optimal in $\mathcal{M}_{\text{LSC}}^{\text{CCS}}$.*

Theorem 18 (Pareto Optimality is Trivial). *Every policy is Pareto optimal in any $\mathcal{M} \supseteq \mathcal{M}_{\text{LSC}}^{\text{CCS}}$.*

The proof proceeds as follows: for a given policy π , we construct a set of ‘buddy environments’ that reward π and punish other policies. Together they can defend against any policy $\tilde{\pi}$ that tries to take the crown of Pareto optimality from π .

Proof. We assume $(0, 0)$ and $(0, 1) \in \mathcal{E}$. Moreover, assume there is a policy π that is not Pareto optimal. Then there is a policy $\tilde{\pi}$ such that $V_\rho^{\tilde{\pi}}(\varepsilon) > V_\rho^\pi(\varepsilon)$ for some $\rho \in \mathcal{M}$, and

$$\forall \nu \in \mathcal{M}. V_\nu^{\tilde{\pi}}(\varepsilon) \geq V_\nu^\pi(\varepsilon). \quad (6)$$

Since $\pi \neq \tilde{\pi}$, there is a shortest and lexicographically first history h' of length $k - 1$ consistent with π and $\tilde{\pi}$ such that $\pi(h') \neq \tilde{\pi}(h')$ and $V_\rho^{\tilde{\pi}}(h') > V_\rho^\pi(h')$. Consequently there is an $i \geq k$ such that $\gamma_i > 0$, and hence $\Gamma_k > 0$. We define the environment μ that first reproduces the separating history h' and then, if $a_k := \pi(h')$ returns reward 1 forever, and otherwise returns reward 0 forever. Formally, μ is defined by

$$\mu(e_{1:t} \mid e_{<t} \parallel a_{1:t}) := \begin{cases} 1, & \text{if } t < k \text{ and } e_t = e'_t, \\ 1, & \text{if } t \geq k \text{ and } a_k = \pi(h') \text{ and } r_t = 1 \text{ and } o_t = 0, \\ 1, & \text{if } t \geq k \text{ and } a_k \neq \pi(h') \text{ and } r_t = 0 = o_t, \\ 0, & \text{otherwise.} \end{cases}$$

The environment μ is computable, even if the policy π is not: for a fixed history h' and action output $\pi(h')$, there exists a program computing μ . Therefore $\mu \in \mathcal{M}_{\text{LSC}}^{\text{CCS}}$. We get the following value difference for the policies π and $\tilde{\pi}$, where r'_t denotes the reward from the history h' :

$$V_{\mu}^{\pi}(\epsilon) - V_{\mu}^{\tilde{\pi}}(\epsilon) = \sum_{t=1}^{k-1} \gamma_t r'_t + \sum_{t=k}^{\infty} \gamma_t \cdot 1 - \sum_{t=1}^{k-1} \gamma_t r'_t - \sum_{t=k}^{\infty} \gamma_t \cdot 0 = \sum_{t=k}^{\infty} \gamma_t = \Gamma_k > 0$$

Hence $V_{\mu}^{\tilde{\pi}}(\epsilon) < V_{\mu}^{\pi}(\epsilon)$, which contradicts (6) since $\mathcal{M} \supseteq \mathcal{M}_{\text{LSC}}^{\text{CCS}} \ni \mu$. \square

Note that the environment μ we defined in the proof of Theorem 18 is actually just a finite-state POMDP, so Pareto optimality is also trivial for smaller environment classes.

6 Discussion

6.1 Summary

Bayesian reinforcement learning agents make the trade-off between exploration and exploitation in the Bayes-optimal way. The amount of exploration this incurs varies wildly: the dogmatic prior defined in Section 3.2 can prevent a Bayesian agent *from taking a single exploratory action*; exploration is restricted to cases where the expected future payoff falls below some prespecified $\epsilon > 0$.

In the introduction we raised the question of whether AIXI succeeds in various subclasses of all computable environments. Interesting subclasses include sequence prediction tasks, (ergodic) (PO)MDPs, bandits, etc. Using a dogmatic prior (Theorem 7), we can make AIXI follow any computable policy as long as that policy produces rewards that are bounded away from zero.

- In a sequence prediction task that gives a reward of 1 for every correctly predicted bit and 0 otherwise, a policy π that correctly predicts every third bit will receive an average reward of 1/3. With a π -dogmatic prior, AIXI thus only predicts a third of the bits correctly, and hence is outperformed by a uniformly random predictor.

However, if we have a constant horizon of 1, AIXI *does* succeed in sequence prediction (Hutter, 2005, Sec. 6.2.2). If the horizon is this short, the agent is so hedonistic that no threat of hell can deter it.

- In a (partially observable) Markov decision process, a dogmatic prior can make AIXI get stuck in any loop that provides nonzero expected rewards.
- In a bandit problem, a dogmatic prior can make AIXI get stuck on any arm which provides nonzero expected rewards.

These results apply not only to AIXI, but generally to Bayesian reinforcement learning agents. Any Bayesian mixture over reactive environments is susceptible to dogmatic priors if we allow an arbitrary reweighing of the prior. A notable

	$K_U(U')$	$K_{U'}(U)$
Indifference prior (Theorem 6)	$K(U) + K(m) + O(1)$	m
Dogmatic prior (Theorem 7)	$K(U) + K(\pi) + K(\varepsilon) + O(1)$	$\lceil -\log_2 \varepsilon \rceil$

Table 1: Upper bounds to compiler sizes of the UTMs used in the proofs. $K_U(U')$ is the number of extra bits to run the ‘bad’ UTM U' on the ‘good’ UTM U , $K_{U'}(U)$ is the number of extra bits to run U on U' , and $K(U)$ is the length of the shortest program for U on U .

exception is the class of all ergodic MDPs with an unbounded effective horizon; here the Bayes-optimal policy is *strongly asymptotically optimal* (Hutter, 2005, Thm. 5.38): $V_\mu^\pi(\mathfrak{x}_{<t}) - V_\mu^*(\mathfrak{x}_{<t}) \rightarrow 0$ as $t \rightarrow \infty$ for all histories $\mathfrak{x}_{<t}$.

Moreover, Bayesian agents might still perform well at learning: AIXI’s posterior belief about the value of its own policy π_ξ^* converges to the true value while following that policy (Hutter, 2005, Thm. 5.36): $V_\xi^{\pi_\xi^*}(\mathfrak{x}_{<t}) - V_\mu^{\pi_\xi^*}(\mathfrak{x}_{<t}) \rightarrow 0$ as $t \rightarrow \infty$ μ -almost surely (on-policy convergence). This means that the agent learns to predict those parts of the environment that it sees. But if it does not explore enough, then it will not learn other parts of the environment that are potentially more rewarding.

6.2 Natural Universal Turing Machines

In Section 3 we showed that a bad choice for the UTM can have drastic consequences, as anticipated by Sunehag and Hutter (2014). Our negative results can guide future search for a *natural* UTM: the UTMs used to define the indifference prior (Theorem 6) and the dogmatic prior (Theorem 7) should be considered unnatural. But what are other desirable properties of a UTM?

A remarkable but unsuccessful attempt to find natural UTMs is due to Müller (2010). It takes the probability that one universal machine simulates another according to the length of their respective compilers and searches for a stationary distribution. Unfortunately, no stationary distribution exists.

Alternatively, we could demand that the UTM U' that we use for the universal prior has a small compiler on the reference machine U (Hutter, 2005, p. 35). Moreover, we could demand the reverse, that the reference machine U has a small compiler on U' . The idea is that this should limit the amount of bias one can introduce by defining a UTM that has very small programs for very complicated and ‘unusual’ environments. Unfortunately, this just pushes the choice of the UTM to the reference machine. Table 1 lists compiler sizes of the UTMs constructed in this paper.

6.3 Optimality of General Reinforcement Learners

Theorem 18 proves that Pareto optimality is trivial in the class of all computable environments; Corollary 13 and Corollary 14 show that maximal Legg-Hutter

Name	Issue/Comment
μ -optimal policy	requires to know the true environment μ in advance
Pareto optimality	trivial (Theorem 18)
Balanced Pareto optimality	dependent on UTM (Corollary 13 and Corollary 14)
Self-optimizing	does not apply to $\mathcal{M}_{\text{LSC}}^{\text{CCS}}$
Strong asymptotic optimality	impossible (Lattimore and Hutter, 2011, Thm. 8)
Weak asymptotic optimality	BayesExp (Lattimore, 2013, Ch. 5), but not AIXI (Orseau, 2010)

Table 2: Proposed notions of optimality (Hutter, 2002; Orseau, 2010; Lattimore and Hutter, 2011) and their issues. Weak asymptotic optimality stands out to be the only possible nontrivial optimality notion.

intelligence (balanced Pareto optimality) is highly subjective, because it depends on the choice of the UTM: AIXI is not balanced Pareto optimal with respect to all universal mixtures. Moreover, according to Corollary 15, any computable policy is nearly balanced Pareto optimal, save some $\varepsilon > 0$. For finite lifetime discounting, there are UTMs such that every policy has maximal intelligence (Theorem 6). The self-optimizing theorem (Hutter, 2002, Thm. 4 & Thm. 7) is not applicable to the class of all computable environments $\mathcal{M}_{\text{LSC}}^{\text{CCS}}$ that we consider here, since this class does not allow for self-optimizing policies. Therefore no nontrivial and non-subjective optimality results for AIXI remain (see Table 2). We have to regard AIXI as a *relative* theory of intelligence, dependent on the choice of the UTM (Sunehag and Hutter, 2014).

The underlying problem is that a discounting Bayesian agent such as AIXI does not have enough time to explore sufficiently; exploitation has to start as soon as possible. In the beginning the agent does not know enough about its environment and therefore relies heavily on its prior. Lack of exploration then retains the prior’s biases. This fundamental problem can be alleviated by adding an extra exploration component. Lattimore (2013) defines BayesExp, a *weakly asymptotically optimal policy* π that converges (independent of the UTM) to the optimal value in Cesàro mean: $\frac{1}{t} \sum_{k=1}^t (V_{\nu}^*(\mathbf{x}_{<k}) - V_{\nu}^{\pi}(\mathbf{x}_{<k})) \rightarrow 0$ as $t \rightarrow \infty$ ν -almost surely for all $\nu \in \mathcal{M}_{\text{LSC}}^{\text{CCS}}$.

But it is not clear that weak asymptotic optimality is a good optimality criterion. For example, weak asymptotic optimality can be achieved by navigating into traps (parts of the environment with a simple optimal policy but possibly very low rewards that cannot be escaped). Furthermore, to be weakly asymptotically optimal requires an excessive amount of exploration: BayesExp needs to take exploratory actions that it itself knows to very likely be extremely costly or dangerous. This leaves us with the following open question: *What are good optimality criteria for generally intelligent agents* (Hutter, 2009, Sec. 5)?

A List of Notation

$:=$	defined to be equal
\mathbb{N}	the natural numbers, starting with 0
\mathbb{Q}	the rational numbers
\mathbb{R}	the real numbers
t	(current) time step, $t \in \mathbb{N}$
k	some other time step, $k \in \mathbb{N}$
q, q'	rational numbers
$\mathbb{1}_x$	the characteristic function that is 1 for x and 0 otherwise.
\mathcal{X}^*	the set of all finite strings over the alphabet \mathcal{X}
\mathcal{X}^∞	the set of all infinite strings over the alphabet \mathcal{X}
\mathcal{X}^\sharp	$\mathcal{X}^\sharp := \mathcal{X}^* \cup \mathcal{X}^\infty$, the set of all finite and infinite strings over the alphabet \mathcal{X}
$x \sqsubseteq y$	the string x is a prefix of the string y
\mathcal{A}	the finite set of possible actions
\mathcal{O}	the finite set of possible observations
\mathcal{E}	the finite set of possible percepts, $\mathcal{E} \subset \mathcal{O} \times \mathbb{R}$
α, β	two different actions, $\alpha, \beta \in \mathcal{A}$
a_t	the action in time step t
o_t	the observation in time step t
r_t	the reward in time step t , bounded between 0 and 1
e_t	the percept in time step t , we use $e_t = (o_t, r_t)$ implicitly
$\mathfrak{e}_{<t}$	the first $t-1$ interactions, $a_1e_1a_2e_2 \dots a_{t-1}e_{t-1}$ (a history of length $t-1$)
h	a history, $h \in (\mathcal{A} \times \mathcal{E})^*$
ϵ	the history of length 0
ε	a small positive real number
γ	the discount function $\gamma : \mathbb{N} \rightarrow \mathbb{R}_{\geq 0}$
m	lifetime of the agent if $\Gamma_{m+1} = 0$ and $\Gamma_m > 0$
Γ_t	a discount normalization factor, $\Gamma_t := \sum_{k=t}^{\infty} \gamma_k$
$\pi, \tilde{\pi}$	policies, $\pi, \tilde{\pi} : (\mathcal{A} \times \mathcal{E})^* \rightarrow \mathcal{A}$
π_ν^*	an optimal policy for environment ν
V_ν^π	the ν -expected value of the policy π
V_ν^*	the optimal value in environment ν
$\Upsilon_\xi(\pi)$	the Legg-Hutter intelligence of policy π measured in the universal mixture ξ
$\underline{\Upsilon}_\xi$	the minimal Legg-Hutter intelligence
$\overline{\Upsilon}_\xi$	the maximal Legg-Hutter intelligence
\mathcal{M}^{CCS}	the class of all chronological conditional semimeasures
$\mathcal{M}_{\text{LSC}}^{\text{CCS}}$	the class of all lower semicomputable chronological conditional semimeasures
ν, ρ	lower semicomputable chronological conditional semimeasures (LSCCSs)
U	our reference universal Turing machine

U'	a ‘bad’ universal Turing machine
w	a universal prior, $w : \mathcal{M}_{\text{LSC}}^{\text{CCS}} \rightarrow [0, 1]$
p, p'	programs on a universal Turing machine in the form of finite binary strings
ξ	the universal mixture over all environments $\mathcal{M}_{\text{LSC}}^{\text{CCS}}$ given by the reference UTM U
ξ'	a ‘bad’ universal mixture over all environments $\mathcal{M}_{\text{LSC}}^{\text{CCS}}$ given by the ‘bad’ UTM U'

B Additional Material

Lemma 19 (Linearity of V_ν^π in ν). *Let $\nu = q\rho + q'\rho'$ for some $q, q' \geq 0$. Then for all policies π and all histories $\mathfrak{x}_{<t}$,*

$$V_\nu^\pi(\mathfrak{x}_{<t}) = q \frac{\rho(e_{<t} \parallel a_{<t})}{\nu(e_{<t} \parallel a_{<t})} V_\rho^\pi(\mathfrak{x}_{<t}) + q' \frac{\rho'(e_{<t} \parallel a_{<t})}{\nu(e_{<t} \parallel a_{<t})} V_{\rho'}^\pi(\mathfrak{x}_{<t}).$$

Proof. We use the shorthand notation $\nu_t := \nu(e_{1:t} \parallel a_{1:t})$. Since $\Gamma_t \rightarrow 0$ as $t \rightarrow \infty$ we can do ‘induction from infinity’ by assuming that the statement holds for time step t and showing that it then holds for $t - 1$.

$$\begin{aligned}
& V_\nu^\pi(\mathfrak{x}_{<t}) \\
&= \frac{1}{\Gamma_t} \sum_{e_t \in \mathcal{E}} (\gamma_t r_t + \Gamma_{t+1} V_\nu^\pi(\mathfrak{x}_{1:t})) \frac{\nu_t}{\nu_{t-1}} \\
&= \frac{1}{\Gamma_t} \sum_{e_t \in \mathcal{E}} \left(\gamma_t r_t \frac{\nu_t}{\nu_{t-1}} + \Gamma_{t+1} \frac{\nu_t}{\nu_{t-1}} V_\nu^\pi(\mathfrak{x}_{1:t}) \right) \\
&= \frac{1}{\Gamma_t} \sum_{e_t \in \mathcal{E}} \left(q \gamma_t r_t \frac{\rho_t}{\nu_{t-1}} + q' \gamma_t r_t \frac{\rho'_t}{\nu_{t-1}} + q \Gamma_{t+1} \frac{\rho_t}{\nu_{t-1}} V_\rho^\pi(\mathfrak{x}_{1:t}) + q' \Gamma_{t+1} \frac{\rho'_t}{\nu_{t-1}} V_{\rho'}^\pi(\mathfrak{x}_{1:t}) \right) \\
&= \frac{q}{\Gamma_t} \frac{\rho_{t-1}}{\nu_{t-1}} \sum_{e_t \in \mathcal{E}} (\gamma_t r_t + \Gamma_{t+1} V_\rho^\pi(\mathfrak{x}_{1:t})) \frac{\rho_t}{\rho_{t-1}} \\
&\quad + \frac{q'}{\Gamma_t} \frac{\rho'_{t-1}}{\nu_{t-1}} \sum_{e_t \in \mathcal{E}} (\gamma_t r_t + \Gamma_{t+1} V_{\rho'}^\pi(\mathfrak{x}_{1:t})) \frac{\rho'_t}{\rho'_{t-1}} \\
&= q \frac{\rho_{t-1}}{\nu_{t-1}} V_\rho^\pi(\mathfrak{x}_{<t}) + q' \frac{\rho'_{t-1}}{\nu_{t-1}} V_{\rho'}^\pi(\mathfrak{x}_{<t}) \quad \square
\end{aligned}$$
